

Description of the DELCODE 1000 FADScore data

FADScores are calculated by applying a mask, obtained from the Novelty activation of a young control group with the same MRI task, to the novelty activation T maps of the old subjects. The difference of the mean T values outside and inside this mask gives a similarity measure. For further details see Düzel et al (2011).

The underlying mask in the young control group can be obtained by applying a threshold to the T-value map from the second level model. We generated two different masks: one by using Familywise Error Correction (SPM12), at a level of $p < 0.01$, which results in a T-value threshold of $T > 5.87$. Using this map, the value for 'FADScores_FWE' was calculated for each old subject. The other variable, the 'FADScores_T8' values, was generated using a much more conservative mask in the young control group, at a T-value level of $T > 8.0$.
